ESR and susceptibility studies of highly oriented pyrolytic graphite–OsF$_6$ (C$_{10}$OsF$_6$) stage-1 graphite intercalated compounds are reported. The anisotropy in both ESR and magnetization are interpreted in terms of a quartet ground state of Os$^{5+}$, 5$d^3$ configuration, in axial local symmetry. The results yield information about charge transfer, anisotropic exchange, spin-orbit coupling, crystal-field splittings, and molecular orientation.

Bartlett, McCarron, McQuillan, and Thompson$^1$ have reported recently on the magnetic susceptibility of powdered samples of C$_6$OsF$_6$ graphite intercalated compound (GIC). Their results indicate Curie-Weiss behavior above $T = 20$ K, but a significant deviation from a Curie-Weiss law below $T = 20$ K. From their susceptibility data, Bartlett et al.$^1$ have concluded that the graphite-OsF$_6$ chemical reaction can be formulated as

$$nC + OsF_6 ightarrow C_n^+OsF_6^-.$$  

The present work uses the magnetic OsF$_6^-$ intercalant ions (5$d^3$ configuration) as a probe to study the ESR and susceptibility of highly oriented pyrolytic graphite (HOPG)–OsF$_6$ with emphasis on stage-1 compounds.$^2$ Our results indicate large anisotropies in the magnetic properties which could not have been seen before in powdered samples. The data are analyzed using a crystal-field model and important information is obtained concerning the intercalant species, the local symmetry and orientation, as well as on the spin-spin anisotropic exchange.

The intercalation procedure was carried out as described by Bartlett.$^1$ A high-quality (001) x-ray diffraction pattern enables us to identify the stages.$^1$ The ESR was carried out in the X-band frequency range over the temperature range between 1 and 300 K. We use a finger-tip helium Dewar for measurements below 4 K but a Helitrans helium-flux system above 4 K. The susceptibility measurements were performed by using a vibrating-type magnetometer (2 K $< T < 300$ K) at the Hebrew University. Some measurements were performed also by using the superconducting quantum interference device (SQUID) at Bar-Ilan University down to $T = 2$ K. The main results on stage-1 HOPG–OsF$_6$ (C$_{10}$OsF$_6$) can be summarized as follows.

The ESR spectra exhibit a single anisotropic line below $T = 50$ K. The intensity of this line is roughly inversely proportional to the temperature, indicating Curie-like spins. Figure 1 exhibits the ESR spectra for various magnetic field orientations $\theta$ with respect to the $\overline{c}$ axis. As can be clearly seen the ESR lines exhibit Dysonian line shape$^3$ with $A/B$ values of about 3–6 (the $A/B$ ratio is defined by Feher and Kip$^3$). The strong axial anisotropy of the ESR line could be expressed in terms of anisotropic effective $g$ value as follows:

$$g_{\parallel} = g_\perp \cos^2 \theta + g_\perp \sin^2 \theta,$$

where $\theta$ measures the angle between the magnetic field $\overrightarrow{H}$ and the $\overline{c}$ axis of the HOPG slab. The parallel and perpendicular $g$ factors are $g_\parallel = 1.65 \pm 0.05$ and $g_\perp = 3.25 \pm 0.05$. These $g$ factors are temperature independent and no effects were observed using different methods of cooling such as field cooling or zero-field cooling. The ESR linewidth $\Delta H$ versus angle $\theta$ exhibits a shallow minimum around $\theta = 60^\circ$, approximately. The ESR linewidth increases almost linearly with increasing temperature. The thermal broadening $b$ [$b = \delta(\Delta H)/\delta T$] was found to depend on sample orientation. Particularly, we found $b = 9 \pm 2$ G/K for $\overrightarrow{H}$ parallel to the $\overline{c}$ axis ($\overrightarrow{H} \parallel \overline{c}$) and $b = 6 \pm 1$ G/K for $\overrightarrow{H}$ perpendicular to the $\overline{c}$ axis.

FIG. 1. ESR line shape of HOPG–OsF$_6$ (C$_{10}$OsF$_6$) stage 1 at $T = 6$ K for various orientations $\theta$. $\theta$ measures the angle between the magnetic field $\overrightarrow{H}$ and the $\overline{c}$ axis ($H_0 = 2600$ G; $\nu = 9139$ MHz).
in the temperature range $1 < T < 30$ K. The observation of slight anisotropic thermal broadening might suggest anisotropic ion-conduction electron exchange interaction.

The results described in Fig. 1 are for freshly prepared samples. We found, however, that the ESR linewidth broadens dramatically (by at least a factor of 3) for samples kept inside quartz tubing for a period of several months, although the spin density as extracted from susceptibility measurements almost does not change. These changes in the ESR linewidth are associated with dramatic broadening of the (001) x-ray diffraction spectra. We were not able to observe the free-carrier resonance (electrons and holes) in any of the C/OsF$_6$ GIC even for high stage samples. Although the emphasis here is on stage-1 GIC, higher stages exhibit very similar ESR features.

The magnetization of HOPG-OsF$_6$ depends strongly on both temperature and sample orientation. It is almost isotropic at high temperatures but strongly anisotropic at low temperatures and independent of the method of cooling. The magnetization as a function of field strength at various temperatures (down to $T = 2$ K) shows a linear behavior confirming the absence of magnetic order above $T = 2$ K. The anisotropic magnetization yields an anisotropic susceptibility. Figure 2 describes the inverse susceptibilities $1/x_L$ (circles) and $1/x_B$ (triangles) for $\bar{H} \parallel \bar{c}$ and $\bar{H} \parallel \bar{c}$, respectively. We note that $1/x_B$ versus temperature roughly exhibits a straight line. The longitudinal inverse susceptibility $1/x_B$ exhibits a fast increase with increasing temperature at low $T (T < 20$ K). At higher temperatures ($T > 30$ K) both $x_B$ and $x_L$ can be described in terms of a Curie-Weiss law: $x_a = C/(T + \theta_a)$ ($a = L, B$) with $\theta_B = 40$ K and $\theta_L = 10$ K. Note also that at high temperatures the slopes of $1/x_B$ and $1/x_L$ vs $T$ are very similar, indicating an isotropic magnetic moment. Using $C = N \mu_B^2 / 3k_B$, we estimate an effective magnetic moment $\mu_{dtr} = 3.2 \mu_B$ from the high-temperature data in Fig. 2.

Our experimental results above strongly suggest that the magnetic properties of HOPG-OsF$_6$ (stage 1) can be explained in terms of quartet ground state of the Os $^{53}$, $S_d^2$ configuration, in an axial symmetry (a slightly distorted octahedral crystal field). Such a configuration has been discussed extensively in the past. The quartet is a result of admixture of a ground-state orbital singlet and excited triplet by the spin-orbit coupling. The energy levels of this quartet can be described in terms of the following spin Hamiltonian with an effective spin $S = 1/2$: $H = S_m^2 + 1/2 (H + S_m - H - S_m)$

$$H = g \mu_B [H_S + 1/2 (H + S_m - H - S_m)] + D [S^2 - 1/4 S(S + 1)]$$

where $g$ and $D$ are given in terms of the spin-orbit coupling $\lambda$ and the singlet-triplet splitting $\Delta$ as:

$$g = 2 (1 - 8 \lambda / \Delta); \quad D = 4 \lambda^2 / \Delta$$

Diagonalization of the $4 \times 4$ matrix associated with (2) yields the energy levels of the quartet. Particularly for $\bar{H} \parallel \bar{c}$ we find, in the first approximation, $g_\parallel \mu_B H << 2D$:

$$E_\parallel (\pm 1/2) = -D \pm 1/2 g_\parallel \mu_B H$$

$$E_\parallel (\pm 3/2) = +D \pm 1/2 g_\parallel \mu_B H$$

For $\bar{H} \parallel \bar{c}$ we find, in the first approximation:

$$E_\perp (\pm 1/2) = -D \pm g_\perp \mu_B H - \frac{1}{16} g^2 \mu_B^2 H^2$$

$$E_\perp (\pm 3/2) = +D + \frac{1}{16} g^2 \mu_B^2 H^2 / D$$

It is clearly seen from (4) and (5) that in zero field the quartet splits into two doublets ($\pm \frac{1}{2}$ and $\pm \frac{3}{2}$) with energy splitting of $2D$. The $g$ values, $g_\parallel$ and $g_\perp$, of the ground-state doublet for $\bar{H} \parallel \bar{c}$ and $\bar{H} \parallel \bar{c}$, respectively, can be extracted from the relation $g_\parallel = [E(\pm 1/2) - E(\pm 3/2)] / \mu_B H$, where $E_\parallel (\pm 1/2)$ are given by (4) and (5). We find $g_\parallel = g$ and $g_\perp = 2g$. Thus, the spin Hamiltonian (2) correctly predicts the experimental ratio $g_\parallel / g_\perp = 2$ as well as the angular dependence of the $g$ value. The observation of a Curie-Weiss behavior at high temperatures indicates the importance of the spin-spin exchange interaction. We have modified, therefore, the spin Hamiltonian (2) to include Heisenberg-type exchange interaction in the molecular field approximation. We write

$$H_{MF} = g \mu_B [H_S + \lambda_B M_B] S_1 + (H_S + \lambda_L M_L) S_1 + D [S^2 - 1/4 S(S + 1)]$$

where $\lambda_B$ and $\lambda_L$ are related to the exchange parameters $J_\parallel$ and $J_\perp$, respectively, as follows:

$$\lambda_B = J_\parallel / g^2 \mu_B^2 N; \quad \lambda_L = J_\parallel / g^2 \mu_B^2 N$$

In the molecular field approximation the susceptibility can be expressed as

$$x_\alpha = x_\alpha ^{(0)} / (1 - \lambda_B x_\alpha ^{(0)})$$

where $x_\alpha ^{(0)}$ is the susceptibility in the absence of spin-spin exchange interaction. For $x_\alpha ^{(0)}$ we write the standard formula:

$$x_\alpha ^{(0)} = (N/2Z) \sum_{\alpha} (-dE_{\alpha} ^{(0)}/dH) \exp(- E_{\alpha} ^{(0)}/k_B T)$$

where the energy levels $E_{\alpha} ^{(0)}$ ($\alpha = \parallel, \perp$) are given by Eqs. (4) or (5); $Z$ is the partition function, $N$ the Avogadro
number, and \( k_B \) the Boltzmann factor. At the high-temperature limit \((k_B T \gg D, g \mu_B H)\) the susceptibility (8) can be written as a Curie-Weiss function:

\[
\chi = C/(T + \theta) \equiv C/(T + \theta_a),
\]

where \( C = g^2 \mu_B^2 S(S + 1)/3k_B \) and \( \theta_a \) are given by

\[
\begin{align*}
\theta_a &= -C \lambda + \frac{1}{2} D = -\frac{5}{4} J_{\parallel} + \frac{1}{2} D, \\
\theta_a &= -C \lambda - \frac{1}{2} D = -\frac{5}{4} J_{\perp} - \frac{1}{2} D.
\end{align*}
\]

(10)

It is seen that the \( \theta_a \) depend on both the exchange parameters and the crystal field splitting. The solid line in Fig. 2 represents a reasonable fit of our model, Eqs. (8) and (9), to the experimental susceptibilities. In the fitting procedure we have used the value of \( g = 1.65 \) from the ESR data and have searched for the best unknown parameters \( D, J_{\parallel}, \) and \( J_{\perp} \). Our best fit yields \( D = 13 \text{ K}, J_{\parallel} = -16 \text{ K}, J_{\perp} = -12 \text{ K} \). Knowledge of \( D = 13 \text{ K} \) and \( g = 1.65 \) enables one to estimate the spin-orbit coupling \( \lambda \) and the singlet-triplet splitting \( \Delta \) using (3). We find \( \lambda = 149 \text{ K} \) and \( \Delta = 6792 \text{ K} \). Note, also, that at high temperatures the isotropic magnetic moment is given by \( \mu_{\text{eff}} = g \mu_B S(S + 1) \). Using \( g = 1.65 \) and \( S = \frac{1}{2} \), we find a theoretical value for the magnetic moment:

\[ \mu_{\text{eff}} = 3.2 \mu_B. \]

This is in excellent agreement with experiment. Using (10) together with \( J_{\parallel} = -16 \text{ K} \) and \( J_{\perp} = -12 \text{ K} \) the Curie-Weiss temperatures are found to be \( \theta_a = +31 \text{ K} \) and \( \theta_1 = 10 \text{ K} \), in good agreement with experiment.

The observation of relatively large exchange parameters but the absence of magnetic ordering down to 2 K is a remarkable feature. HOPG–OsF\(_6\) is, thus, different from other magnetic GIC such as HOPG–FeCl\(_3\), HOPG–CoCl\(_3\), HOPG–NiCl\(_2\), and HOPG–CoCl\(_2\), which exhibit magnetic order.\(^7\) It should be noted that in all these magnetic GIC the pristine intercalant species are magnetic and retain this property in the intercalation compound. HOPG–OsF\(_6\) is prepared from the gas phase of OsF\(_6\) and its magnetic properties are due to the charge transfer [Eq. (1)], i.e., there is no correlation with the magnetic properties of the starting materials.

Following are our conclusions.

\*Present address: Physics Department, University of California at Santa Barbara, Santa Barbara, California 93106.

\^4D. Vakin (unpublished).

\^9See, for example, M. Suzuki et al., Synth. Met. 8, 43 (1983); C. H. Simon et al., ibid. 8, 53 (1983); H. Suematsu et al., ibid. 8, 23 (1983); M. Elahi et al., ibid. 8, 35 (1983).

(1) The combined experiments provide evidence that the intercalant species are almost completely in the form of OsF\(_6\). The prediction of Bartlett et al. is correct.\(^1\) There is a charge transfer of one electron per each OsF\(_6\) formula. Previous studies of GIC with fluorides such as HOPG–AsF\(_3\) have shown significantly smaller charge transfer per molecule.\(^10\) This is probably associated with the fact that the chemical reaction does not always go to completion in some of these GIC fluorides.

(2) The experimental results indicate the existence of a well-defined crystal field and a well-defined orientation of the intercalant species. The suggestion of Bartlett et al.\(^1\) that the \( C_3 \) axis of the OsF\(_6\) ion is parallel to the \( \bar{z} \) axis (see Fig. 5 in Ref. 1) is consistent with our observation for freshly prepared samples.

(3) The susceptibility study provides evidence for anisotropic antiferromagnetic spin-spin exchange interaction. The crystallographic studies of Bartlett et al.\(^1\) on C\(_4\)OsF\(_6\) indicate an hexagonal structure with unit cell dimensions of \( a \sim 4.9 \text{ Å} \) and \( c \sim 8.1 \text{ Å} \).\(^7\) For a single OsF\(_6\) molecule per unit cell in stage-1 compounds, the in-plane distance between OsF\(_6\) moieties is significantly shorter than this distance along the \( c \) axis. This might suggest that the exchange parameters \( J_{\parallel} \) and \( J_{\perp} \) are dominated by in-plane interactions.

(4) The absence of long-range magnetic order down to 2 K for relatively large in-plane Heisenberg exchange parameters \( (J_{\parallel} = -16 \text{ K}, J_{\perp} = -12 \text{ K}) \) might suggest that HOPG–OsF\(_6\) is truly two-dimensional magnet and the long-range magnetism is destroyed by fluctuations, according to the classical Mermin-Wagner theorem.\(^11\) We are currently conducting measurements on higher stages to check critically if indeed HOPG–OsF\(_6\) is a realization of two-dimensional magnetic system according to the Mermin-Wagner theorem.

The authors wish to thank Dr. Moore of Union Carbide for providing the HOPG. This work was supported by Stiftung Volkswagenwerk.
